E.3 Research Design	xv
E.4 Analysis	xviii

A Data Collection Process

First, we outline our data collection process, which is also described in [citation omitted]. We collected our data via automated textual analysis through the Python programming language. This method allows us to quickly and reliably collect data on state supreme court decisions. Our computer program extracts critical pieces of information from text files of state supreme court opinions and converts the information into quantitative data. This data collection method produces reliable measures of state supreme court decision making and facilitates a wide range of empirical analyses.

We began by obtaining every state supreme court decision for each state from 1995 through 2010 through the Lexis-Nexis Academic online database. Lexis-Nexis includes both published and unpublished opinions for those state courts of last resort that allow unpublished decisions (see Serfass and Cranford (2001) for details on the variation in publishing rules across states). However, for two reasons, we do not utilize unpublished opinions in the creation of our ideal point estimates. First, and most importantly, these unpublished opinions do not report any disagreement between the justices. Accordingly, they all appear as unanimous decisions and are, therefore, omitted from our calculation of ideal point estimates. Second, unpublished opinions are generally used when a court does not “modify,” “clarify,” “explain,” or even “call attention to” existing law (Serfass and Cranford 2001, 252). In some states, this practice is an explicit rule; in other states it is an informal norm. Therefore, these opinions are, by definition, unrelated to the creation of legal policy in which we are interested. Accordingly, unpublished opinions are comparable to voice votes in legislatures, which are always disregarded for the creation of ideal point estimates.

We then created automated textual analysis programs (or “scrapers”) using the Python programming language to extract data from these text files. Because the formatting of published opinions varies between state supreme courts, it was necessary to create fifty-two unique scrapers, one for

each state supreme court.¹ We then utilized these scrapers to extract critical pieces of information on each state supreme court case and convert the text information into a spreadsheet with data for each state. Our data include the following pieces of information for each case in our dataset:

- The name of the case, case citation, and LexusNexis citation.
- The day, month, and year of the decision.
- The prior history, procedural posture, and disposition of the case in text format.
- The area of law at issue in the case as identified by the first Lexis-Nexis headnote.
- The opinion author and dissent author(s), if any.
- The vote of each judge in the case.

In order to create accurate Python code to extract this data, we began by hand-coding the dockets of a small sample of states across different years. Our hand-coding revealed that the format of the pertinent information in the dockets was relatively uniform for most of our variables; however, our initial hand-coding revealed that the dockets varied widely in the reporting of judges' votes both across and within states. For example, in 14 states, the dockets only listed the names of opinion-writing judges, dissenting justices, and those not participating. In these cases, we imputed the concurring votes of other sitting judges into the data. This process required a precise roster of service dates by all judges in these 14 states. To complete this task, we utilized State Court websites, Lexis-Nexis news searches, and direct contact with state courts to ensure that we accurately imputed the votes of judges who were actually on the court. Our Python scrapers code each judge in a specific year with a concurring vote unless he or she was noted in the decision as dissenting, dissenting in part, or not participating. When judges joined or left the court in the middle of a year, we manually deleted concurring votes by those judges in any case in which they did not sit based

¹We have separate scrapers and data for the Courts of Criminal Appeals and State Supreme Courts in Oklahoma and Texas.

on the date of the oral argument. Consequently, our data identify the name of each judge sitting on each case and indicate whether that judge voted with the majority or dissented in the case.

We also corrected our data to account for changes in the structure, organization, and procedures of each state supreme court. For example, the Nevada judicial system lacks an intermediate court of appeals. Consequently, the Nevada Supreme Court hears most appeals in the state. To accommodate the court's large docket, the Nevada state legislature expanded the court from five members to seven in 1997. Even more importantly, the court hears most cases in panels of three judges. Accordingly, we adapted our scraper for the Nevada Supreme Court to detect and report only the specific panel of judges that heard each case.

Another coding problem arose when two or more judges on the same state supreme court shared a common surname. Most dockets typically list only the last name of sitting judges; however, in some states judges with the same surname are noted with a first initial. This practice was initially problematic for our scrapers because we used punctuation marks to demarcate judge names. To solve this problem, we revised our Python code to merge the first initial into the surname so that the program could distinguish between judges. For example, in Minnesota, Paul Anderson and Barry Anderson have served concurrently since 2004. Our scraper first changed their names in the dockets to "Panderson" and "Banderson" so that it could then easily distinguish between them to code their votes. We did the same type of change for individuals with two capital letters in their last name—for example, "McDonald" was changed to "Mcdonald".

Once we completed a scraper for specific state, we began a multi-step process to maximize the accuracy of our final data. Our Python scrapers produced four separate documents—(1) the data, (2) a list of cases and votes with any dissenting votes, (3) a list of cases with any judges listed as "not participating" or "recused", and (4) a list of cases in which any error was encountered while running the Python code. We then assigned a research assistant to review documents 2-4 and compare these reports to the data (document 1). If our data was missing any of the dissenting votes or non-participants, we went back to the dockets, looked for common errors, and adjusted the Python code accordingly. We then repeated these steps until the data correctly identified all

of the dissenting votes and non-participants. Lastly, we assigned a research assistant to compare about 25 cases in each year from the original dockets with our finalized data to ensure accuracy.

A.1 Reliability and Validity

We next turn our attention to reliability and validity checks of our data. Because the time span of our data collection effort overlaps with that of Brace and Hall, we are able to conduct a reliability check on our data by comparing it to the data they collected for the years 1995 through 1998. We randomly sampled 500 cases from the Brace and Hall data and compared their hand-coded data to the same 500 cases in our computer generated data. We then conducted a validity check of our data by assigning a research assistant to compare the same 500 cases in our data to the actual dockets from which we extracted the information.² We specifically examined between 14-18 pieces of information from each dataset: the case title, citation, majority opinion author, dissenting opinion author, and votes from 5-9 judges in each state depending on court size.³ We code the votes of the judges as either joining or dissenting from the decision of the court. Results from both the reliability and validity checks are reported in Table A1.

The first important aspect of Table A-1 is the high level of agreement between our data and the Brace and Hall data. With the exception of the case citations, our data corresponds with the Brace and Hall data at over 93.9% for each variable. With regard to case citations, our data agrees with the Brace and Hall data in only 84.6% of cases. An examination of these cases indicates that almost every case of disagreement between our data and the Brace and Hall data is the result of human coder error in the Brace and Hall data. In many cases of disagreement, the Brace and Hall data has typos, inaccurate values, or missing alphabetic prefixes that some states include in their citations. When we match our data to the dockets, our citations match up 98.8% of the time. In fact, our validity check indicates that our automated scraper program was remarkably accurate at coding the data. Agreement between our data and the actual dockets was higher than 98% for each

²To ensure the accuracy of our validity check, we assigned a second research assistant to compare 100 of these cases with the actual dockets. These two research assistants agreed in 100% of the cases they examined.

³The manner in which we scraped our data and Brace and Hall coded their data does not allow for a direct comparison across all pieces of information. For example, they provide numeric values of the individual steps in the appeals process, whereas we provide the direct text.

variable.

[Insert Table A-1 here]

Within the reliability checks, our largest concern is with the actual behavior of the judges. We match our data to the Brace and Hall data in 93.9% of all judge votes; however, our validity check suggests that our automated program outperforms the hand-coding in the Brace and Hall data. Most of the discrepancies between our data and the Brace and Hall data are the result of their human coders failing to include a judge in a case when we accurately pick up the vote. Overall, the Brace and Hall data missed 141 votes in these cases; our program missed only 46 votes.

This is not to say our data is without comparative disadvantages. The Brace and Hall data includes many nuances that our data collection process fails to detect. For example, we do not have substitute judges in our data. We only include the full-time judges. If a temporary judge becomes a full-time judge at some point in their career, we can pick up their votes when they were substitute judges. The Brace and Hall data codes the votes of all substitute judges; however, these votes comprise only a small minority of votes on these courts.

Our data collection process also encounters difficulties when judges retire after hearing a case, but before the decision is written. Our automated textual analysis software is not always able to detect the nuance required to code this information. For example, many states list the judges who heard oral arguments for the case; if the judge retires before the decision is written, this information is indicated in a footnote. Our data does not pick up these footnotes and, therefore, misrepresents these votes. This problem arises in fewer than 10 cases in our sample.⁴

Overall, our data has high levels of validity when compared to the actual dockets, meaning our scraping procedure yields data of remarkably high quality. Additionally, our data are quite reliable

⁴Below are two examples of cases with a footnote designating a special judge or a non-participating judge that we do not accurately pick up in our data.

JUDGES: Shearing, C.J., Rose, J., Sullivan, D.J.⁴ SPRINGER, J., dissenting.

⁴ The Honorable Jerry V. Sullivan, Judge of the Sixth Judicial District Court, was designated by the Governor to sit in the place of the Honorable A. William Maupin, Justice. Nev. Const. art. 6.

JUDGES: Before Carson, Chief Justice, and Gillette, Van Hoomissen, Fadeley, Unis,** Graber, and Durham, Justices.

** Unis, J., did not participate in this opinion.

compared to the Brace and Hall data obtained using human coders. The most important aspect of the data, the judges' votes, is highly valid and reliable.

B Court Medians Over Time

Figure A-1 shows the dynamic element of our scaled ideal points. The graphs plot the dynamic common space median of each court for the time period 1995–2010. For ease of visibility, we separate the 52 dynamic medians into four groups of 13 state courts.

[Insert Figure A-1 here]

C Dynamic IRT Ideal Points

In Figures A-2–A-14 we graph our dynamic IRT ideal points of the justices not included in the main text. The graphs show considerable change over time in individual judges' ideal points.

[Insert Figures A-2–A-14 here]

D Additional Fit Statistics

Here we report additional results regarding the fit statistics presented in the main text. First, we present an additional out-of-sample predictive test generated and evaluated through cross-validation based solely on our unscaled dynamic IRT measure. Secondly, we report the in-sample fit statistics with our unscaled IRT measure. Finally, we report correlations between our unscaled measure, CFscores, and PAJID.

D.1 Cross-Validated Fit Statistics with the Unscaled Dynamic IRT Measure

Table A-2 replicates Table 1 from the main text, but with the unscaled version of our dynamic IRT measure.

[Insert Table A-2 here]

The results show that our unscaled dynamic IRT measure generally performs the best among the three alternatives. In this case the model with the IRT measure produces the largest CC and

APRE for 44 of the 52 state courts. The CFscores produce the best fit for seven of the eight remaining states according to both statistics. On average, the IRT-based measure's CC is 0.879, versus 0.812 for PAJID and 0.834 for CFscores. The average APRE values reflect the same pattern: 0.568 (IRT), 0.345 (PAJID), and 0.420 (CFscores).

D.2 In-Sample Fit Statistics

Table A-3 reports the fit statistics using the unscaled dynamic IRT measure and the full sample of cases (i.e., without cross-validation).

[Insert Table A-3 here]

The results again show that our unscaled dynamic IRT measure generally performs the best among the three alternatives; the model with that measure produces the largest fit statistics for 47 of the 52 state courts, with the CFscores producing the best fit in the other five states. On average, the IRT-based measure's CC is 0.893, versus 0.835 for PAJID and 0.856 for CFscores. The average APRE values reflect the same pattern: 0.594 (IRT), 0.385 (PAJID), and 0.458 (CFscores).

D.3 Explaining the SDIRT Measure's "Losses"

Table 1 in the main text shows a few instances in which PAJID or CFscores beat our measure with respect to the fit statistics. To the best of our knowledge there is nothing systematic across these states that would lead us to believe this is a major problem. What follows are the best explanations we can produce for each state. We do not consider Iowa in depth because the CFscores only beat our measure based on the proportion correctly classified, and even then it is by a very small amount (0.001).

In Michigan the CFscores benefit from a great deal of information compared to other states. When looking at the DIME database, on average, Michigan judges receive contributions from 825 individuals. This is far greater than the national mean of 276 contributors per judge. Furthermore, only Florida has a higher average number of contributors. In Florida, however, the data only cover four judges, while Michigan has 63 judges receiving contributions. Moreover, the maximum number of contributors in Michigan for a judge is 3,981. This is the second highest maximum number

of contributors in DIME. Thus, we suspect that our IRT estimates are contributing a smaller proportion of the total information compared to other states. In other words, adding the IRT information does not contribute much to what is already in the CFscores in that state.

In Alaska and Indiana, the left-right constraints set for the ideal point estimation may be causing higher levels of uncertainty in the ideal points. In each of those states, there is only a single judge who was appointed by a Republican governor, allowing us to only place one judge as the right constraint. In both cases there is not much data for this judge. In Indiana, this judge retired in 1996, and in Alaska this judge was not appointed until 2008. These issues could be contributing to the lower classification rate and APRE in the cross-validation tests. However, this is not to say that the scores in those states are necessarily wrong or skewed. As evident in the fit tests, they are still very close to the CFscores in predictive capacity.

Missouri is the only state in which the PAJID scores outperform both our measure and the CFScores. When looking at our scaled ideal points in Missouri, there are three distinct clusters of judges: a conservative group, a liberal group, and a moderate group. These judges were almost all appointed by governors ideologically similar to them: John Ashcroft (extreme conservative), Mel Carnahan, (extreme liberal), and Bob Holden (moderate). Thus, Missouri may simply be an example in which the theoretical framework of PAJID works well. These judges' voting choices very closely reflect the composition of the Missouri government at the time of their appointments.

It is also important to note that the magnitude of fit performance favors our measure. In the five state courts in which our measure gets beat on the proportion correctly classified, it is by an average of 0.01. In the four state courts in which our measure gets beat on APRE, it is by about 0.03, on average. In the other 47 and 48 courts, respectively, our measure outperforms the second best measure by an average of 0.048 and 0.163.

D.4 Correlations Between Measures

In Table A-4, we report the correlation coefficients between the PAJID scores and our unscaled dynamic IRT ideal points and between the CFscores and our unscaled dynamic IRT ideal points. Our measure has a moderately strong correlation with the CFscores, with an overall correlation

coefficient of 0.4494. The state variation ranges from -0.1989 in California to a high of 0.8752 in Wisconsin. In contrast, the PAJID scores have a weak correlation with our IRT ideal points, with an overall coefficient of -0.2492 . In a number of states, the correlation coefficients are very close to 0, indicating no relationship, while in a few states (e.g., Oklahoma, Delaware, and Missouri) there is a negative correlation stronger than -0.8 .

[Insert Table A-4 here]

E Application: Assessing Policy Responsiveness

Numerous studies find that elite policy decisions often tend to reflect popular opinion (e.g., Erikson, MacKuen, and Stimson 2002; Erikson, Wright, and McIver 1993; Fiorina 1974; Froman 1963). In fact, a variety of policymakers appear to follow public sentiment, including legislators (Stimson, MacKuen, and Erikson 1995), executives (Canes-Wrone and Shotts 2004), bureaucrats (Rabinovich 2008), and judges (McGuire and Stimson 2004). Yet, scholars continue to debate which mechanisms drive this process—why does public policy mirror popular opinion?

Undoubtedly, this mass-elite policy connection is partially driven by the changing composition of governing institutions. Policy decisions by public officials tend to reflect popular sentiment as those officials are replaced over time, whether through electoral turnover (Hakhverdian 2010; Stimson, MacKuen, and Erikson 1995), judicial appointment (Norpoth and Segal 1994), or the selection of bureaucratic agents (Brehm and Gates 1997). After securing office, elite decisions may correlate with shifts in popular opinion due to the independent influence of social forces (Collins, Norton, Manning, and Carp 2008; Giles, Blackstone, and Vining 2008) or interest group pressure (Carpenter 2002; Collins 2007). It is also possible that public officials actually influence popular opinion (Franklin and Kosaki 1989; Kernell 1997; Sigelman 1980; Tulis 1988). However, individual policymakers may also directly respond to shifts in popular preferences for several different reasons.

First, the replacement of some officials may pressure others to comply with changing popular preferences. The system of checks and balances deliberately empowers separate institutions

to exert influence over one another: executives can veto legislative enactments, legislatures can thwart executive policies, and both can sanction judges. Consequently, even unelected officials, such as bureaucrats and judges, may respond to popular preferences due to pressure from other officials (Stimson, MacKuen, and Erikson 1995; Weingast 1984). For example, U.S. Supreme Court justices may react to public opinion because they fear legislative override of their decisions (Ferejohn and Shipan 1990; Gely and Spiller 1990), retributive sanctions against their institutional power (Casillas, Enns, and Wohlfarth 2011; Epstein and Knight 1998), or nonimplementation of their decisions (Hall 2014; McGuire and Stimson 2004). Thus, even without a personal reelection incentive, appointed judges may have good reason to heed popular sentiment. However, evidence of the High Court's responsiveness is tentative (Flemming and Wood 1997; Mishler and Sheehan 1993), disputed (Giles, Blackstone, and Vining 2008; Norpoth and Segal 1994; Segal and Spaeth 2002), and possibly restricted to a small subset of cases (Hall 2014).

Alternatively, electoral accountability may be the critical element inducing policy responsiveness. The goal of reelection is a powerful motivation; indeed, “[elections are] where representative form[s] of government begin and end” (Fenno 1996, 9; see also Mayhew 1974; Miller and Stokes 1963). Accordingly, policymakers may adjust their decisions to reflect shifts in public opinion in order to improve their odds of reelection (Erikson, MacKuen, and Stimson 2002; Gordon and Huber 2002; Kousser, Lewis, and Masket 2007). In fact, the threat of electoral defeat may be so powerful that it prompts responsiveness irrespective of a legislator's electoral experiences (Fiorina 1974). For example, Bartels finds that “representatives who win with 100% of the vote appear to be about as responsive to constituency opinion as those who win with 51% of the vote” (1991, 468; see also Gulati 2004). This behavior may arise because larger vote margins do not necessarily indicate greater incumbent security (Jacobson 1987). Consequently, “incumbents are subject to random terror” (Ansolabehere, Brady, and Fiorina 1992, 36) and, therefore, respond to popular preferences regardless of their personal electoral experiences.

E.1 Testing the Determinants of Policy Responsiveness

Several practical limitations hinder the study of how elections and competition influence elite behavior. First, it is difficult to compare the responsiveness of public officials who do and do not have to stand for reelection because most major political offices do not vary in selection mechanism. Some studies overcome this problem by testing the influence of electoral rules and institutional design in cross-national studies (e.g., Hobolt and Klemmensen 2007; Roberts and Kim 2011); however, this research examines only a few countries that vary on a wide range of social and political dimensions. The complex nature of cross-national research makes it difficult to isolate institutional effects. Even more importantly, these studies compare different types of electoral systems rather than elected versus unelected offices. Accordingly, few previous studies have directly assessed the influence of elections on policy responsiveness (cf. Besley and Coate 2003).

Second, assessing the effects of electoral competition on public officials is difficult because competition (e.g., in the form of a challenger or a viable challenger) is endogenous to incumbent behavior (Gordon and Huber 2007). That is, incumbents may respond to public pressure when they face competition, but if they respond to public pressure they should avoid competition. Consequently, testing the effect of actual competition in the next election on incumbent behavior is fraught with problems. An alternative approach is to use the vote margin of another race (such as presidential vote share) as a proxy for two party competition (Griffin 2006; Gulati 2004). This approach avoids the endogeneity concern, but sacrifices some theoretical fit. Our interest here is in state supreme court judges' perceived electoral threats, not generic evaluations of whether the two major parties are competitive among the electorate.⁵

To overcome these limitations, we follow several groundbreaking studies that focus on state courts of last resort (e.g., Brace and Hall 1995; Hall 1992). These institutions offer several advantages for the study of electoral competition and policy responsiveness. First, state supreme court elections and decisions attract very little public attention (Cann and Wilhelm 2011; Mathias 1990).

⁵Previous electoral experiences may also suffer from problems of endogeneity (Gulati 2004; Sullivan and Uslander 1978).

Accordingly, these institutions pose a conservative test for responsiveness and the potential influence of competition (Gordon and Huber 2007, 110). Second, despite their relatively low public profile, these courts possess important policymaking responsibilities. Therefore, unpopular rulings may attract negative attention from other officials. Third, these courts share numerous similarities in operation, organization, and social context to facilitate meaningful comparisons, yet, they vary significantly in selection mechanism. Fourth, state supreme court justices usually represent the same constituency. This institutional feature enables us to disentangle a state's level of two-party competition from a judge's personal electoral experiences.

Judicial institutions also pose a special normative dilemma for policy responsiveness. In the legislative and executive branches, responsiveness is a hallmark of democratic legitimacy; however, in courts of law, responsiveness lies in tension with principles of justice, precedent, and judicial independence. Accordingly, judges may tend to be less responsive than other public officials, and a judge's responsiveness may be moderated by her personal *legal* experiences in addition to her electoral experiences. Do legal principles win out over popular pressure and electoral incentives? Or do state supreme court justices tend to behave like other politicians? And, perhaps most importantly, what institutional structures and individual experiences moderate judicial responsiveness? To examine these questions, we turn to research on policy responsiveness in state courts.

E.2 Dynamic Representation in State Courts of Last Resort

Numerous studies argue that elections prompt state judges to follow popular preferences. Most of this literature focuses on the manner in which judges reach the bench and retain their jobs. The American states vary widely in judicial selection mechanisms. Seven states elect justices through partisan elections, 15 hold nonpartisan elections, and 16 appoint members initially, then hold retention elections to remain on the court. Finally, 12 states use gubernatorial or legislative appointment, with many of these states requiring reappointment after varying term lengths or a mandatory retirement age (American Judicature Society 2013).⁶ These selection differences influ-

⁶Reappointment mechanisms vary across these 12 states. Massachusetts and New Hampshire allow judges to serve until they turn 70 and then must retire. Connecticut, Delaware, Maine, New Jersey, New York, and Rhode Island have gubernatorial reappointment processes that include a confirmation vote by one or both legislative chambers. Vermont

ence the choices judges make (Brace and Hall 1990; Hall and Brace 1989; Brace and Hall 1993; Langer 2002). Elected trial court judges (Gordon and Huber 2007; see also Huber and Gordon 2004) and state supreme court justices (Brace and Hall 1995, 1997; Brace, Hall, and Langer 1999, 2001; Brace and Boyea 2008) are both more responsive to public preferences than judges selected through appointment.

Other studies emphasize electoral competition; i.e., state judges may respond to public opinion only when they rationally anticipate future competition. These studies test the effects of competition in different ways. For example, judges tend to follow popular preferences when they near the end of their terms (Hall 1992; Caldarone, Canes-Wrone, and Clark 2009) and when general partisan competition in the state is high (Brace and Hall 1995, 1997). These findings suggest that judges respond to public opinion because they anticipate future competition; however, they do not capture rational expectations at the individual level. State-wide competition and the proximity of a judge's reelection contest are only indirectly related to that judge's rational expectations regarding future competition.

Secondly, mandatory retirements may influence the behavior of both appointed and elected judges. In thirty-three states, judges may not serve past a certain age (typically 70 or 72). Extant literature on behavior of state courts often overlooks mandatory retirement as an influence on judicial behavior. In other institutions, however, there is mixed evidence on the influence of retirement on roll call behavior (Rothenberg and Sanders 2000; Clark and Williams 2013; Wright 2007). The influence of public opinion in state courts may be conditional based on mandatory retirement. The electoral and re-appointment constrain is no longer influencing the behavior of judges.

This rich, extensive literature offers valuable insights into policy responsiveness; yet, this groundbreaking work has been hampered by a lack of available data. For example, some studies examine judicial behavior over only a few years (e.g., Brace and Boyea 2008; Cann and Wilhelm 2011). Because these studies essentially employ cross-sectional rather than longitudinal data, they are unable to test whether judges actually change their voting behavior in response to shifts in pub-

calls for a vote of the general assembly to reappoint a judge. Hawaii requires reappointment by a commission. Finally, Virginia and South Carolina hold legislative elections for both initial appointments and retention.

lic opinion over time. Others include only a small number of states (Hall 1987, 1992, 1995; Brace and Hall 1997) or only states with certain selection mechanisms (Caldarone, Canes-Wrone, and Clark 2009). Finally, many studies focus exclusively on rare case types—namely abortion (Brace, Hall, and Langer 1999, 2001; Caldarone, Canes-Wrone, and Clark 2009) and capital punishment (Brace and Boyea 2008; Brace and Hall 1995, 1997; Canes-Wrone, Clark, and Kelly 2014). As an example, Brace and Boyea’s (2008) analysis of capital punishment decisions uses only 889 out of the 15,000 cases in the State Supreme Court Data Project (SSCDP). More recently, Cann and Wilhelm (2011) use the SSCDP to examine judicial responsiveness across a wide range of issue areas. They find that only judges facing contestable elections respond to the public and then only in “highly visible” cases, which are just 1.3% of the cases in their data (2011, 569).

In short, there is some evidence of policy responsiveness in state supreme courts. However, the research to date often focuses on a small subset of salient cases, employs cross-sectional analyses for a brief time period, examines only a few states, and/or does not incorporate individual electoral experiences. Our study improves on previous work in several important ways. First, we test responsiveness in every state supreme court by generating aggregate measures of decision making based on every non-unanimous decision in these courts. Second, we test whether justices’ voting behavior responds to, rather than simply correlates with, popular preferences by modeling the dynamic effects of public opinion over time. Finally, we test whether state supreme court justices anticipate electoral competition or change their behavior when they are faced with mandatory retirement from the court.

E.3 Research Design

Our goal is to test the effects of citizen preferences on state supreme court voting behavior. Because our ideal point estimates cover a period of 16 years, our measure of judicial voting facilitates an assessment of dynamic effects across time. This approach provides better leverage on the question of whether judges are indeed *responding* to citizen opinion rather than simply voting in a manner that is correlated with it. Indeed, a problem for many cross-sectional studies of representation is determining whether a political official’s behavior is consistent with constituency

preferences because he or she is responding to their views or because he or she shares those views already and was elected to office because of that agreement. As Kuklinski and Stanga state, “[t]he use of data collected at a single point in time...precludes separating agreement resulting from simple elite-mass sharing of policy attitudes and that due to the actual response of officeholders” (1979, 1091). Our data and estimation strategy avoid this problem by modeling *changes* in judges’ voting behavior over time as a function of *changes* in citizen preferences over time.

To capture these dynamic effects, we use single-equation error correction models (ECM) with judge-level random effects.⁷ The dependent variable in our models is the change in the scaled ideal point for each individual judge in a given year (the SDIRT measure from the main text). Positive values of the ideal point estimates indicate a judge moving in a conservative direction, and negative values indicate a move in a liberal direction. To test the moderating role of judicial selection mechanisms, we estimate four separate ECMs: one for states with partisan elections, one for states with non-partisan elections, one for states with initial appointment and unchallenged retention elections, and one for states with lifetime appointments.

Our use of ECMs provide a strong link between our theoretical expectations and our empirical model. The ECM estimates a coefficient for both the differenced and lagged values of each predictor.⁸ This allows us to examine both short-term effects, in which a change in public preferences produces an immediate change in judges’ voting behavior, and long-term effects, in which the past value of public preferences influences current and future voting behavior through an equilibrium relationship (De Boef and Keele 2008). Allowing for separate estimation of short- and long-term effects accounts for the fact that the judiciary is a reactive branch of government. While a court can have substantial influence on policy, it cannot exert such influence until a relevant case is argued before it. Thus, while immediate responses to public preferences are possible, our strategy also allows for the possibility that a change in the public’s preferences may take several years to

⁷Regardless of selection type, each of our proposed models contains cointegrated data, necessitating the use of the error correction approach (Persyn and Westerlund 2008).

⁸A lagged independent variable in an ECM is a re-parameterized estimate of the error term from regressing Y on X . Consequently, the ECM models the extent to which the disequilibrium between X and Y is adjusted or corrected through changes in Y .

influence judges' behavior.

Our primary independent variable is the measure of *state mood* as computed by Enns and Koch (2013). This measure relies on over 500 different surveys with more than 700,000 respondents to calculate yearly estimates of state mood through multilevel regression and poststratification (MRP, see also Lax and Phillips 2009; Park, Gelman, and Bafumi 2004). To date, this is the only measure of yearly state-level mood that relies on public opinion polls rather than proxies for the electorate's preferences or pooled multi-year estimates (e.g., Erikson, Wright, and McIver 1993; Berry, Ringquist, Fording, and Hanson 1998; Carsey and Harden 2010).⁹

We hypothesize that responsiveness to public opinion is not only a function of selection method, but also a judge's personal electoral experiences. Utilizing data from *The Judicial Elections Data Initiative* (JEDI), we include a variable indicating whether the judge is up for election in the next year. We then interact the state mood and election variables to measure how changes in public opinion exert different influences when a judge will face an election in the next year

Furthermore, we include an indicator variable if a judge is in the year prior to mandatory retirement. We collected the data of birth of each judge over this 16 year time period, as well as the mandatory retirement age of each state if applicable. We then interact the state mood and mandatory retirement variable to examine if judges respond different to public mood when they are forced to leave the bench.

Finally, we include fixed effects to account for state-level variation; that is, we include dichotomous indicator variables for each state taking on the value of 1 for observations within that state and 0 otherwise. These fixed effects set different intercepts for each state in order to account for the possibility that decision making in certain states tends to be more or less liberal than decision making in other states. Thus, our models test the effects of our predictor variables *within* states. This is an important choice because there are many differences between states that might affect the decisions presented to judges, and thus the estimated ideal points. For example, some state

⁹We reversed the original coding of this variable to match the ideological direction of our judge-level indicator. This variable now ranges from 38.194 to 74.35, with lower values indicating a more liberal state and higher values representing a more conservative state. The mean state mood is 62.02 with a standard deviation of 5.56.

courts have discretionary dockets while others do not. Our modeling strategy accounts for these differences because all between-state variance is explained by the fixed effects.¹⁰

E.4 Analysis

We present the coefficient estimates and standard errors from our four models in Table A-5. The columns report the results from states with partisan elections, non-partisan elections, retention elections, and judicial appointment, respectively. Overall, the results in Table A-5 comport with the expectations that retiring judges will behave differently, but we do not find evidence indicating that judges are responsive to public preferences.

[Insert Table A-5 here]

More specifically, we do not see a change in judicial behavior due to an upcoming election. In each of our models, the interaction between public mood and an election year is insignificant. In partisan election states, the coefficient is in the right direction, however this relationship fails to reach traditionally accepted levels of significance.

Mandatory retirement, however, negatively influences policy responsiveness in both partisan election and appointment states, but not in non-partisan or merit selection states. As evident in Table A-5, Columns 1 and 4, judges who face mandatory retirement change their voting behavior in the opposite direction of public mood. This relationship reaches traditional levels of statistical significance.

We plot the marginal effects of this interaction in Figure A-15 and A-16. In both of these figures, judges in non-retirement years see no significant movement in their judicial behavior, as evident by the relatively flat line. Judges in retirement years, however, in both graphics exhibit a sharp countermajoritarian behavior when faced with retirement. This lends evidence to retirement lifting the potential pull of the public on judges behavior.

[Insert Figure A-15 here]

¹⁰We estimated alternative models controlling for term length and the number of seats on the court. Both of these variables are statistically insignificant in each of our models. Furthermore, the overall model fit declines in the over-specified models. We therefore only report results from the analyses outlined above.

[Insert Figure A-16 here]

Overall, this substantive application highlights a key benefit of our new SDIRT measure of judicial ideal points: its dynamic nature. A common problem in studies on representation is that static data cannot provide evidence for or against responsiveness. For example, previous work shows that state public opinion is positively correlated with judges' voting behavior in elected states but not non-elected states (e.g., Brace and Boyea 2008). However, these cross-sectional associations do not provide evidence that judges' voting behavior actually moves with, or responds to, changes in public opinion. In this application we examined actual responsiveness to public opinion through an ECM. The result is a closer connection between the theoretical framework of most representation studies and the empirical test. In this case, we find no evidence that judges are responsive across several different types of selection mechanism. In fact, we find that in some circumstances—namely mandatory retirement—judges' voting behavior actually moves in a countermajoritarian direction.

Means	0.879	0.812	0.834		0.568	0.345	0.420		100

Note: Cell entries report cross-validated model fit statistics for our unscaled dynamic IRT ideal point measure, PAJID, and CFscores. The first four columns give the proportion of votes correctly classified by the model with each measure and the best fitting-measure. The next four columns give the aggregate proportional reduction in error by the model with each measure and the best-fitting measure. The final column gives the number of court cases used in model fitting for each state court. South Carolina is omitted from the CFscores computations due to sparse data.

Table A-3: In-Sample Vote Prediction Model Fit Statistics with Unscaled Dynamic IRT

State Court	Proportion Correctly Classified				Aggregate Proportional Reduction in Error				Court Cases
	IRT	PAJID	CFscores	Best Fit	IRT	PAJID	CFscores	Best Fit
